

***Trichomanes speciosum* Willd.**

Killarney Fern (gametophyte)

Native

GB & England: Least Concern

Schedule 8

VC5 Scarce; VC6 Absent

Perennial felt-like mat of branching filaments, unique amongst European ferns in its ability to exist forever as a gametophyte. Restricted to dark, humid recesses, crevices and caves in a range of acidic to neutral rocks. The independent gametophytic generation of this species was only discovered in Britain in 1989, by Don Farrar, however by 1997 it had been recorded in 38 vice-counties (Rumsey *et al.*, 1998). Found in Somerset for the first time in 2008, by Matt Stribley, at two locations on Exmoor, both in dark, humid rock crevices beside the River Barle. In 2009, a third site was discovered by Fred Rumsey at Holford Glen, in Alfoxton Wood, in the Quantocks, where again the species grows in rock crevices above a stream. This is one of two sites for *Hymenophyllum tunbrigense* in Somerset. In 2011, Matt Stribley discovered gametophytes of *Trichomanes speciosum* in crevices on Colescombe Rocks at Hawkcombe, which is the other Somerset site for *H. tunbrigense*. It was re-found here in 2019 and 2020, in two different monads, by Graham Lavender, who also discovered it in rock crevices at new sites nearby in 2020, at Horner Water and Wilmersham Wood. It is likely to be found on other similar rock outcrops on Exmoor. Somerset sites are within the area of the British and Irish distribution of *T. speciosum*, which is mainly northern and western, with some sites in Sussex.

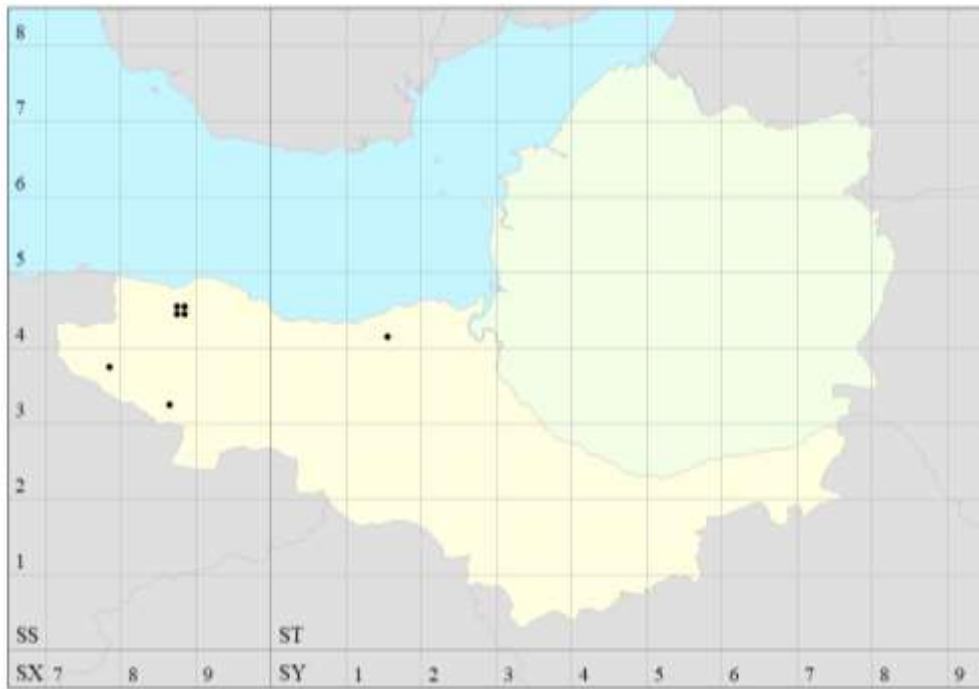

(Following molecular studies, some authors consider this species better placed in the genus *Vandenboschia*.)
